Abstract

A concentrating solar power system is presented which uses hillside mounted heliostats to direct sunlight into a volumetric absorption molten salt receiver with integral storage. The concentrated sunlight penetrates and is absorbed by molten salt in the receiver through a depth of 4–5 m, making the system insensitive to the passage of clouds. The receiver volume also acts as the thermal storage volume eliminating the need for secondary hot and cold salt storage tanks. A small aperture and refractory-lined domed roof reduce losses to the environment and reflect thermal radiation back into the pond. Hot salt is pumped from the top of the tank through a steam generator and then returned to the bottom of the tank. An insulated barrier plate is positioned within the tank to provide a physical and thermal barrier between the thermally stratified layers, maintaining hot and cold salt volumes required for continuous operation. As a result, high temperature thermal energy can be provided 24/7 or at any desired time.

The amount of storage required depends on local needs and economic conditions. About 2500 m$^3$ of nitrate salt is needed to operate a 4 MW$_e$ steam turbine 24/7 (7 h sunshine, 17 h storage), and with modest heliostat field oversizing to accumulate energy, the system could operate for an additional 24 h (1 cloudy day). Alternatively, this same storage volume can supply a 50 MW$_e$ turbine for 3.25 h without additional solar input. Cosine effect losses associated with hillside heliostats beaming light downwards to the receiver are offset by the elimination of a tower and separate hot and cold storage tanks and their associated pumping systems. Reduced system complexity also reduces variable costs. Using the NREL Solar Advisor program, the system is estimated to realize cost-competitive levelized production costs of electricity.

Keywords: Concentrating solar power; Molten salt; Volumetric absorption receiver; Hillside heliostats; Thermal storage

1. Background

A robust solar energy portfolio is likely to include solar thermal systems that enable energy storage with electricity production when there is limited sunlight. Concentrating solar power (CSP) systems that use a central receiver with integral thermal energy storage have the potential to produce 24/7 base load and/or peak electric power. Power towers use heliostats to focus sunlight on a receiver placed...
and steam plant efficiency (Viebahn et al., 2008). Conventional high temperature CSP systems have evolved to use a central tower where a heat transfer fluid circulates through tubes onto which the sunlight is focused. However, maximum allowable fluxes are limited to avoid thermal degradation of the receiver tubing. Lata et al. (2008) cites tradeoffs between tube diameter, wall thickness, receiver durability and pressure drop in conventional tubular receiver designs while describing an external tubular receiver capable of achieving slightly higher maximum fluxes, up to 1.0 MW/m², thereby reducing receiver surface area and losses while increasing overall plant efficiency.

Utilizing molten salts as the working fluid enables simple subsequent thermal storage, due to their high heat capacities and wide operating temperatures. Unfortunately, daily receiver filling requires ancillary heaters and presents additional risks should the salt freeze, requiring electric heat tracing on long piping runs, valves and manifolds. Despite these measures, operating problems still occur; for example, the Solar Two CSP demonstration plant was disabled by frozen salt in pipes (Reilly and Kolb, 2001). Another approach is direct absorption of sunlight by several-centimeter thick salt waterfalls, but the cost of pumps, manifold and piping preheaters, and fluid flow variations as a function of varying solar flux, limited the practicality of such systems (Bohn, 1987).

To minimize receiver fluid pumping losses and enable alternative receiver designs, Rabl (1976) proposed a beam-down reflective tower with a ground-based CSP receiver. Similarly, Yogev (1997) and Epstein et al. (1999) suggested a beam-down system where the light was to be beamed directly into a molten salt/metal filled container. It has even been proposed for tall buildings to use balcony-mounted heliostats to direct sunlight to a receiver placed atop the building (LeBarre, 2010). Since Rabl’s proposal in 1976, significant experimental work has occurred on beam-down towers and ground receivers, especially for reforming materials (Yogev et al., 1998; Segal and Epstein, 2003). The Odeillo solar furnace facility uses a north facing parabola focused on a target built into one wall of a building that holds offices and laboratories.

Sixty-three south-facing flat mirror heliostats track the sun’s movement and focus it down on the north facing parabola (Trombe and Le Phat Vinh, 1973). NREL also has a high-flux solar furnace system where heliostats aim light towards a ground-based secondary reflector system that redirects and concentrates the sunlight to a small aperture receiver, although up to 10% of the energy is lost with each reflection (Skinrood et al., 1974). These systems achieve high concentrations and receiver temperatures with large, precision secondary optical elements – whose cost has prevented the commercial adoption of beam-down CSP.

Conventional thermal storage systems require two molten salt storage tanks, each capable of storing the entire system volume (Herrmann et al., 2004). In traditional CSP systems, cost-savings have been obtained with single tank systems relying on temperature stratification via natural thermocline formation (Pacheco et al., 2002). Copeland and Green (1983) and Copeland et al. (1984) have shown “rafted thermocline” designs effective at boosting thermal stratification in water tanks, with suggested designs for molten salt thermal storage tanks. However, passive rafted thermoclines would rely on two parameters difficult to control in high temperature molten salt tanks: maintaining neutral buoyancy at the hot–cold thermocline interface; and a near perfect seal with the side walls to prevent leakage around the divider raft. Indeed, tests performed in water showed the neutrally buoyant raft design may display instabilities and tilt and/or jam in the storage tank. Demonstration CSP plants without storage have typically been designed with a co-firing gas turbine scheme to enable continued operation when the solar system is down (European Commision, 2005).

2. CSPonD: collocated receiver and storage system

Here we present a new system with heliostats mounted on a hillside that beam light directly into an open container of molten salt at the base of the hill, or into a one-bounce system with the receiver at the top of the hill (Fig. 1). A small aperture in the receiver lets the sunlight penetrate the surface of the large molten high temperature salt pond. Volumetric absorption enables a simpler receiver design
with a free surface molten salt pond, without high-pressure, high-flow molten salt pumps, capable of high temperature storage. The molten salt surface is self-healing – tolerating high solar flux transients without irreparable sudden or cumulative damage to the receiver. Concentrated Solar Power on Demand (CSPonD) could provide 24/7 power and thus help fill a critical need in solar power, that of energy storage (Slocum et al., 2010). Incoming concentrated solar flux directed at the aperture can follow one of three paths: refracted into the molten salt; reflected off the salt surface towards the inner surface of the receiver lid; or directly impinged on the inner surface of the lid (Fig. 2). An important design goal is to shape the cover to function as a diffuse reflecting concentration booster, not unlike the compound parabolic concentrator units used in beam down towers (Bassett and Derrick, 1981; Derrick and Bassett, 1985).

For the near term we consider a salt commonly used in CSP plants: sodium–potassium nitrate (e.g., Hitec® solar salt: 60/40 wt.% NaNO3–KNO3) which has a low melting point of 222 °C. Although above 593 °C solar salt decomposes and becomes corrosive and dangerous, systems have been built and operated to pump it between hot and cold storage tanks and a steam generator (Herrmann et al., 2004). The power block, including salt pumps, heat exchanger/steam generator and power generation device, for a nitrate salt based CSPonD system will be very similar to those that can be commercially obtained. Hence, for a near term CSPonD system, a steam power cycle will be assumed with peak steam temperatures of 500–540 °C.

Both the molten salt pond and the lid will exchange heat with each other and to the environment by radiation, convection and conduction; the primary heat transfer mechanism is through radiation. The system cover will be lined with refractory firebrick and backside cooled, so the salt vapor rises and condenses on the inner surface of the cover, akin to frost collecting on evaporator coils within a refrigerator. The resulting white surface will grow until the thickness results in a thermal resistance that condenses the salt vapor, but the surface continually melts and returns liquid salt to the pond. The liquid/solid interface is expected to act as a diffuse reflector to incoming light that reflects off the surface of the salt. Solidified salt has a very high reflectivity in the visible spectrum and behaves nearly as a Lambertian reflector; liquefied salt will be subject to grazing-angle Fresnel surface reflections and as such, much of

Fig. 1. Representative CSPonD sites in White Sands, NM for pond receiver without (A) and with (B) secondary reflector. The CSPonD system simultaneously collects sunlight while also acting as the beam-down optic thereby reducing overall system complexity and cost. Icons illustrate receiver location and discretized terrain sampling locations from elevation data, not an actual heliostat layout. See Noone et al. (2011).

Fig. 2. Cross sections of a CSPonD volumetric absorption molten salt receiver/storage system: (A) Yellow arrows denote light path within receiver. At end of a sunny day the divider plate has moved down and the hot salt region is fully charged. (B) Whereas after prolonged heat extraction without solar input, the divider plate has moved up and the cold side is full. Hot molten salt is pumped as needed from the top of the tank to provide reasonably constant power and temperature input to a steam generator or other power cycle. Colder, yet still liquid salt from the steam generator is returned to the bottom of the tank. (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)
the light impinged onto the lid will be reflected back to the pond. The energy that is transferred to the lid is from lower-temperature, longer wavelength radiation from the salt surface. Only a small fraction of incoming photon energy is converted to thermal energy at the lid.

The vapor pressures of molten salts are fairly low, on the order of 0.001 bar for chloride salts at 900 °C. As a result, the overall fuming rate is low, given as 0.2 kg/m² of exposed salt area per hour for a chloride salt bath at 870 °C (ASM, 1991). For the 5 m deep × 25 m diameter system proposed in the following text, this equates to roughly 100 kg/h, or less than 0.006% of the entire salt mass. Lower temperature nitrate CSPonD systems will have lower salt vapor pressures and mass transfer, and reduced radiative transfer between the salt surface and the lid as compared to higher temperature chloride salt systems. The lid is not depending on mass transfer for cooling – active cooling will be employed to obtain the desired lid operating temperature. Cooling loops would be concentrated in high heat flux regions, and various zones can be employed for temperature control throughout the lid. It may be found that the optimal lid design is not isothermal, but has varying temperature to limit radiative transfer and convective losses. The collected cover energy, unique to CSPonD systems, can vary from 2% to 20% of the incident solar power and this intermediate-temperature heat is used elsewhere in the plant (Ghobeity et al., submitted for publication). The percentage of lid heat extracted depends primarily on the plant layout: hillside topology, operating temperatures, and seasonal and diurnal position of the sun. In a dual-purpose desalination and electricity production plant using the CSPonD concept, heat collected by the cover can be used for preheating feed water to the steam generator or desalination feed water (Goosen et al., 2002; Ghobeity and Mitsos, 2009; Ghobeity et al., submitted for publication).

The top surface of the salt needs to remain at a constant level for consistent solar absorption; hence, the tank is split into two zones with a moving barrier plate. The top zone is the hot salt side, and the bottom zone is the cold salt side. An insulated creep and corrosion resistant alloy plate divides the two sides, providing a physical and thermal barrier between the thermally stratified hot and cold layers within the tank. The light will penetrate deeply and a small fraction of it will impact the highly absorbing divider plate causing convection currents, heating the hot side to a uniform high temperature (Fig. 2). The near neutrally buoyant divider plate is moved axially by small actuators, with negligible power consumption, to maintain the hot and cold salt volumes required for continuous operation. As a result, high-temperature salt can be provided even as the average temperature in the tank decreases (Fig. 3). As the divider plate is lowered when the aperture is open and the tank is being heated by sunlight, colder salt from below moves past the annular clearance space between the barrier plate and tank wall to be reheated. Relative “blow-by” salt velocities are slow (much less than 1 cm/s for a nominal 20 cm annular clearance on the proposed system), accounting for the daily downward motion of the plate displacing fluid and pumped cold salt returning from the heat exchanger. Semenyuk (1983) describes a means to calculate exergy losses for mixing two working bodies differing only in temperature. For a nitrate CSPonD receiver with hot salt at 55 °C, cold salt at 25 °C and ambient temperature of 300 K, the exergetic mixing efficiency (1 = no loss) is found as 0.935; this value approaches 1 for higher temperature CSPonD systems. Mixing losses are incorporated in the worst case estimates of receiver efficiency listed as 0.6 in Table 2.

The salt-filled annular clearance between the loose fitting divider plate and tank walls acts as a buffer by limiting thermal gradients as the divider plate moves. Degradation of the tank walls due to thermal shock is reduced compared to well-sealed barrier thermoclines with sharp thermal interfaces (Copeland et al., 1984). The tank is internally insulated with a 15-cm-thick layer of high-temperature, thermally conductive alloy liner can be employed to reduce axial thermal gradients and shock. Cross-section adapted from Kolb (1993) and Gabbrielli and Zamparelli (2009).
insulated with mortarless insulating refractory brick, whose thermal resistance and mass limits temperature swings at the mild steel tank shell, as depicted in Fig. 4 (Kolb, 1993). If needed, a thin corrugated alloy liner can be employed which minimizes thermal shock and reduces erosion and spalling of the refractory brick in the tank; this internally-insulated design has been shown to be more cost-effective than a stainless steel tank with external insulation (Gabrielli and Zamparelli, 2009). Metallurgical salt baths have proven commercial “super-duty” alumina/silica or pure silica fireclay bricks adequately resist corrosion from molten nitrate or chloride mixtures (ASM, 1991). Recent tests have verified the cyclic stability of silica particles in molten sodium and potassium nitrate at the temperatures considered (Broseau et al., 2005).

Two 90° arcs of heliostats with radius 390 m feeding two apertures on a volumetric molten salt receiver 25 m diameter and 5 m deep containing 4500 tons (2500 m$^3$) of 550 °C molten nitrate salt could power a 4 MW$_{e}$ steam turbine continuously, 24/7 (7 h sunshine, 17 h storage) on a daily basis. In addition, the heliostat field is sized so that for every 10 days of full sun, the system could also run for an addition 24 h on a cloudy day (Table 1). Conservatively, one can assume it takes about 16 m$^3$/MW$_{e}$/h of nitrate salt for non-sunshine operation. The CSPonD system is rated by continuous power production, not peak power as is typical of traditional CSP systems without overnight storage.

Greater power cycle efficiencies can be realized with the use of larger steam turbines. This can be accomplished with larger CSPonD receivers or several smaller units feeding a common power block. However, many locales will favor the use of CSP-generated power for peaking purposes, with greatly reduced storage needs. As such, the same 2500 m$^3$ storage volume can supply a 50 MW$_{e}$ turbine for 3.25 h without additional solar input. After peak demand subsides, heat extraction can be stopped and nighttime losses from the well-insulated receiver are minimal.

The receiver’s “capture efficiency” can be defined as the fraction of incoming energy retained by the receiver – used to heat both the pond and the lid. Aperture size is driven by system sizing and input flux concentration and is used to calculate geometrical view factors and radiative losses to the environment. Other losses include conduction through the tank walls and convection to the outside environment. In general, capture efficiency increases with input flux concentration as the system geometry approaches that of a blackbody. The self-healing nature of the molten salt surface tolerates much higher fluxes than conventional tube based receivers – and can achieve higher efficiencies as heliostat field technology and achievable concentration improves.

High lid temperature leads to reduced capture efficiency due to large radiative and convective losses out of the aperture. However, a higher lid temperature reduces radiative exchange from the salt pond to the lid – effectively keeping more energy in the salt. For example, a 240 °C lid and 550 °C salt temps ($\varepsilon \sim 0.9$), roughly 18 kW/m$^2$ is lost from the salt surface to the lid, 14% of the incoming power when the aforementioned receiver is “on sun” at the design point. With the aperture closed for 16 h, salt-lid radiative transfer would result in nearly 140 MW h of energy transferred to the roof – nearly one-quarter of the 600 MW h (equivalent to 180 MW h electric at $\eta_{th} = 0.30$) storage capacity. This upper bound assumes a fully-exposed salt surface and a constant salt surface temperature. However, high solar concentration enables reductions in exposed salt surface area, further reducing losses and heat gain from the salt to the lid. Also, the pond free-surface will cool due to radiative, as well as internal convective heat transfer while off-sun.

As a result, permanent heat transfer from the pond to the lid will decrease. Additionally, if energy was not extracted from the lid at a sufficient rate, the lid temperature will increase. Low lid thermal mass will result in quicker heat up and reduced nighttime losses. One possible operational strategy would be to slow or stop lid heat rejection towards the end of the day while still on sun, allowing the lid temperature to equilibrate with the salt, reducing radiative transfer. Permanent heat transfer losses are incorporated into the receiver efficiency estimates (0.6–0.9) in Table 2 for the continuous operation CSPonD system examined (i.e., both salt and lid heat rejection running 24/7).

Similarly, large beam down angles (i.e., steeper hillsides) are effective at directing more of the incoming energy into the salt. A steep beam down angle has two effects: the illuminated or projected area of the aperture on the horizontal molten salt pool is decreased, reducing exposed salt area and subsequent losses; and Fresnel reflections off of the salt surface to the lid are reduced. To avoid hot spots and minimize system complexity, natural convection within the salt is needed. This can be designed into the pond using numerical methods (Nave, 2004). Preliminary results using the

The CSPonD system could likely support higher power cycle temperatures should the need arise in the future. Future generation NaCl–KCl CSPonD designs could be considered for high temperature operation and the two zone tank could still be used. Most of the salt handling and power-cycle technology required for a hot chloride salt option for CSPonD has been partly developed for the molten salt nuclear reactor program (Forsberg et al., 2007). Liquid salt pumps have been tested up to 6000 L/min at temperatures exceeding 700 °C (Grindell et al., 1960; Williams, 2006). Multiple CSPonDs could feed a common central power plant (Forsberg and Moses, 2009).

With regard to the stability of the salts, there is a large industrial experience base with molten salts used in the heat treatment of metals (Mehrkam, 1967; ASM, 1991). These high temperature salt baths are open to the atmosphere as metal components are moved in and out of the salt bath (Fig. 5). The heat treating industry has developed standard methods to test the salt, using additives to control salt chemistry, and replacing the salt if the impurity levels are too high. The rate of impurity buildup will be much lower for CSPonD than for a heat treating bath with its daily throughput of steel parts.

The use of quartz windows was considered to help reduce radiation losses and eliminate mass transfer across the aperture. However, as mentioned in literature and as observed in our testing, quartz crucibles in contact with many salts tend to lose their optical clarity with time (Li and Dasgupta, 2000). The salts chosen as appropriate for CSPonD systems have limited toxicological and environmental effects should some condense outside the receiver; however, any system which regularly loses heat transfer fluids (other than steam) to the environment will likely be denied a permit. Fortunately, the salt bath heat treating industry provides guidance. Salt bath furnaces employ ventilation hoods, either offset from the salt surface or directly overhead to capture salt fumes at their source. The salt vapors are drawn into the intake, and condense on the intake plenum. The accumulated salt is scraped off during routine maintenance. A similar system can be installed above the aperture of the CSPonD receiver, perhaps utilizing an intake plenum with an automated salt scraping and
collection system. Salt vapor and thermal losses can also be mitigated with the use of air curtains installed across the aperture (Paxson, 2009).

2.1. Volumetric absorption in molten salts

The light attenuation characteristics of the molten salt are critical as they strongly affect temperature gradients within the salt and overall system design. For example, if the salt is too attenuating, in large deep ponds created for a large amount of storage, forced circulation of the salt could be required to prevent overheating of the top surface of the salt. Conversely, if the salt is found to be too transparent, overheating of the divider plate could occur if it is brought too close to the surface. The attenuation of the salt could be increased with the addition of nanoparticles to the salt, or conversely, impurities that build up with time could affect the behavior of the salt. The attenuation characteristics of the CSPonD candidate molten salts are currently not available. Accordingly, the efforts undertaken to obtain this data are detailed here.

2.1.1. Attenuation measurements in molten salt

Light attenuation in a semi-transparent medium is described by the attenuation (or extinction) coefficient, \( \alpha \) (cm\(^{-1}\)), which represents the probability per unit length that a photon will be removed from the incident beam, either by absorption or scattering (Passerini, 2010). The attenuation coefficient depends on the photon energy, or wavelength, and also on the temperature of the medium. The intensity transmitted through a layer of material of thickness \( d \) is related to the attenuation coefficient by the following equation:

\[
I = I_0 e^{-\alpha d}
\]

where \( I \) and \( I_0 \) are the transmitted and incident intensities, respectively. Eq. (1) can be used to calculate the attenuation coefficient by measuring the intensity of light transmitted through known depths of a molten salt.

A furnace-based apparatus was designed and built to measure optical properties of a number of candidate molten salts at various temperatures and wavelengths (Passerini, 2010). It is capable of operating from room temperature up to 1100 °C. The apparatus and method were validated against published data by comparing results obtained for deionized water at room temperature and Hitec\textsuperscript{®} salt\(^1\) from 250 to 500 °C (Drotning, 1978; Smith and Baker, 1981). Due to the light signal intensity distribution, reliable data were obtained between 400 nm and 800 nm, while for shorter and larger wavelengths the signal to noise ratio drops significantly, making quantitative evaluation of the attenuation coefficients impossible.

For illustrative purposes, the measured attenuation coefficient of a 60/40 wt.% sodium–potassium nitrate mixture at 350 °C has been applied to the reference solar irradiance plot of ASTM G173-03. Fig. 6 shows the result of applying the measured attenuation to this reference solar spectrum for different molten salt depths. At a depth of two meters, 93% of the total solar energy is absorbed by the candidate nitrate salt in the 400–800 nm range. It is important to note that 55% of the terrestrial solar insolation lies in the 400–800 nm range. Extrapolation of this data beyond the 400–800 nm range is difficult. However, it is expected that highly absorbing regions would be in the infrared region at wavelengths greater than 2.5 μm, where the solar irradiance expires. Accordingly, some first order extrapolation could be performed.

2.1.2. Irradiance distribution in receiver

For a central heliostat located on the optical axis of the receiver aperture, the input flux will be restricted to an ellipse of major axis \( D_a \) projected on the salt surface, calculated as

\[
D_a = D_s/\sin \phi
\]

where \( D_s \) is the aperture diameter and \( \phi \) is the nominal beam-down angle measured from horizontal. A portion of the incoming concentrated light is reflected off the molten salt–air interface. This reflected fraction can be calculated from the Fresnel equations describing light as it moves between media of different refractive indices. The reflection coefficients for s- and p-polarized light are

\[
R_s = \left( \frac{\sin(\theta_i - \theta_r)}{\sin(\theta_i + \theta_r)} \right)^2
\]

\[
R_p = \left( \frac{\tan(\theta_i - \theta_r)}{\tan(\theta_i + \theta_r)} \right)^2
\]

The angles that the incident, reflected and refracted rays make to the normal of the interface are given as \( \theta_i \), \( \theta_r \) and \( \theta_s \), respectively, and related by Snell’s Law and the law of reflection.

\(^1\) Costal Hitec is a name brand, ACS reagent grade chemicals were used at the same composition as the Hitec product.
\[ n_{\text{salt}} \sin \theta_i = n_{\text{air}} \sin \theta_i \quad (5) \]

\[ \theta_i = \theta_i \quad (6) \]

where

\[ \theta_i = 90^\circ - \phi \quad (7) \]

Since the incident light is unpolarized, containing an equal mix of s- and p-polarizations, the reflection coefficient, \( R \), is

\[ R = (R_s + R_p)/2 \quad (8) \]

Eq. (8) can be used to find the percentage of the incident energy which is reflected onto the lid. For the sample case of nitrate solar salt with \( \phi = 20^\circ \) and \( n_{\text{salt}} = 1.413 \) (Bloom and Rhodes, 1956), 84.7% of the incoming radiation refracts into the salt while 15.3% reflects onto the lid. The intensity of the refracted light at various salt depths is then found with Eq. (1). Fig. 7 illustrates the incoming solar irradiance distribution for a centralized heliostat aimed at the receiver, simulated using MATLAB. An entire heliostat field array can be aimed to create a circular illumination distribution on the salt surface; much of the incoming radiation will be absorbed near the top of the salt surface and towards the rear of the tank. Hence, it is logical to extract high temperature salt in this location for the power cycle.

2.1.3. Solar simulator testing of a volumetric salt receiver

To test the CSPonD concept, a high-flux large-area solar simulator was designed to achieve output fluxes greater than 60 kW/m² (Codd et al., 2010). Tests were conducted on a small scale receiver tank equipped with a movable divider plate, designed to partition the volumetric molten salt receiver into two thermally separated regions (Fig. 8).

The divider plate provides excellent thermal separation between the hot upper and cold bottom sections. The bare stainless steel top surface of the divider plate absorbs much more energy than the relatively transparent salt; as a result, the hottest region of the receiver is the top surface of divider plate. This creates natural convection cells in the top region thereby preventing overheating of the top surface and maximizing thermal storage in a given volume of salt. Fig. 9 depicts the convection currents within an alternate test receiver detected with a lab-built particle image velocimetry (PIV) system. Indeed, the light penetrating the salt causes heating deep within the sample and convective mixing readily occurs to prevent hotspots.

Due to packaging constraints, the small-scale divider plate test bed utilized a \( \frac{1}{4}'' \) (6.35 mm) rigid silica insulating board affixed to the underside of the stainless steel divider plate. Full scale systems would utilize significantly more insulation, on the order of 10–20 cm, providing a greater thermal resistance and limiting heat transfer while providing the design value of 300 K across the divider plate. In a larger and deeper system, the upper surface of the divider plate will receive less radiation than this small scale experiment. However, with full-scale insulation on the divider plate, conduction through the bottom plate will decrease. It is expected that natural convection into the upper hot salt region will remain of the same magnitude, and a temperature inversion should occur in the hot salt region — accordingly the Nusselt number will remain similar to this experiment. Regrettably, the 60-sun solar simulator was not available to test this concept.

![Fig. 7. Representative solar irradiance distribution for a single heliostat aimed at a CSPonD receiver. A complete heliostat field can be aimed to create a circular illumination distribution on the salt surface.](image-url)
not capable of heating the salt above 380 °C. This was to be expected with high conductive, surface radiative and convective losses for this low-flux test receiver. Full scale systems will utilize much greater flux levels and have significantly reduced system losses, which will increase the hot salt temperatures and the temperature difference across the divider plate.

However, these small scale experiments cannot provide insight to how a full scale machine would truly work. Hence, numerical modeling is required to design the full scale tank and divider plate system, and then testing of a deep tank system.

2.2. Site selection and heliostat placement

There is precedence for the location of heliostats on a hillside to direct sunlight to a secondary reflector, then redirecting the power to a receiver on the ground (Trombe and Le Phat Vinh, 1973); however, up to 10% of the energy is lost with each additional reflection, not to mention high-flux secondary mirror cooling concerns, operation and installation costs. Meanwhile, there appears to have been a “land rush” for acquiring rights to flat, sunny land perceived to be needed for other types of solar power systems, which have increased the overall costs of traditional CSP systems. The system presented here thus reflects the solar energy from a heliostat field on a hillside directly into a receiver. In the northern hemisphere, a south-facing hillside field allows for direct beam-down entry into the molten salt pond as shown in Fig. 1A. These configurations allow for CSP collector fields to be built on otherwise undevelopable, steep terrain hence reducing system costs. Methods used by utility companies for emplacing utility poles on moderately steep terrain can be used for heliostat installation, and automated spray systems can be utilized for cleaning the mirrors. Indeed, one of our important conclusions is conventional power tower systems could benefit from hillside mounted heliostats. A numerical tool was developed to evaluate potential sites for beam up and beam down CSPonD configurations (Noone et al., 2011). For two case studies, White Sands, NM and China Lake, CA, the area investigated is roughly 10,000 km² and optimal receiver locations for the beam-down configuration have efficiencies of 70% and 68%, respectively. In the beam-up configuration, both case studies have optimal receiver locations with efficiencies of 77%. These efficiencies take into account cosine efficiency, shading and blocking losses due to the terrain; optical losses of the heliostats are not included in these results. However, “heliostat overall efficiency”, given in Table 2 as 0.5–0.6, includes heliostat optical losses including reflectivity, mirror shape and tracking errors.

For each case study, one result is included to illustrate an optimal location for a pond receiver for each of two scenarios, (i) reflecting the sunlight up the hill into a secondary reflector at the receiver with an optical efficiency of 0.9, and (ii) reflecting the sunlight down the hill so as to not require a second reflection. Similar results were obtained for both sites, and a summary of the White Sands results are presented in Fig. 10.

Sites with highest efficiency from the White Sands area were shown in Fig. 1. In these sites, the heliostat fields are north (right) of the receiver, represented in the image for visualization of the field extents only, not an actual heliostat layout. The field efficiency of the site with the secondary reflector is calculated to be 77% and the site without is 70%, a difference of 7% despite the 10% loss associated with the grazing angle reflection off the inner surface of the lid. Assuming that 15% of the land can be utilized, and of this land 30% is covered by heliostats, a solar-to-electric efficiency of 22%, and a 24/7 average solar insolation of 200 W/m², the White Sands site could provide 20 GW·e of power 24/7. Similar results are obtained for China Lake.

2.3. Economics

The uncertainty associated with new technologies is very large and therefore a conservative as well as an optimistic economic analysis was conducted. The Solar Advisory
Model (SAM) by NREL was used along with the economic assumptions by US Department of Energy for Call DE-FOA-0000104 set for 2020, including some incentives (Sargent and Lundy, 2003).

The optimistic scenario gives an economical levelized cost of $0.07/kW h, while a conservative estimate is currently prohibitively high with a value of $0.33/kW h (Table 2). It should however be noted that this figure is high compared to present fossil fuel costs, not necessarily high compared to conventional CSP systems. The range of levelized energy cost clearly demonstrates the need for further research, in particular with regards to (i) the detailed design of the pond and lid along with selection of salt and materials, (ii) the best use of the land available via optimal placement of heliostats and (iii) the optimal integration of the pond and lid with the power cycle (and potentially a cogeneration scheme).

3. Conclusions and future work

A CSP system with integral storage has been presented where hillside mounted heliostats direct sunlight into a volumetric absorption molten salt receiver either near the base of the hill where the sunlight can directly penetrate the salt, or at the top of the hill where the light is redirected off the lid of the receiver before it enters the salt. In both cases, salt vapor condenses on the inside surface of the lid to form a self-healing reflective surface.

The concentrated light penetrates and is absorbed in the receiver by molten salt through a distance of 4–5 m which allows for high solar fluxes and is structurally insensitive to cloud cover transients that affect other CSP systems. The receiver has a relatively small aperture with lower secondary heat losses and avoids thermal fatigue associated with boiler tube-type receivers while achieving high temperatures needed for efficient power generation. In addition, the receiver volume also acts as the thermal storage volume. Hot salt is pumped from the top of the tank through a heat exchanger and then back into the bottom of the tank. An insulated plate provides an additional thermal barrier between the thermally stratified hot and cold layers within the tank, and the barrier is moved axially up and down to provide high temperature thermal energy even as the average temperature of the salt in the tank decreases when the sun is not shining.

Fundamental measurements of the optical absorbance properties of molten salt sand bench level experiments indicate viability of the concept. Analysis of hillsides at two southwestern government land sites shows good potential for CSP system development. An economic analysis using NREL’s Solar Advisor program indicates a levelized cost of electricity of $0.07–0.33/kW h.

The next step in the research is to design a 20–100 kWt test receiver that has an aperture size to receive light from a typical concentrating heliostat, so a commercial array can be easily modified and used without needing additional concentrating optics at the aperture. This receiver would, however, be designed with the full anticipated depth of a larger system, so the optical penetration and convective mixing properties anticipated for the MWt sized CSPonD system can be evaluated.

Acknowledgments

This work is part of an interdisciplinary collaboration between the Cyprus Institute, the University of Illinois at Urbana Champaign, the Electricity Authority of Cyprus, and the Massachusetts Institute of Technology. Generous graduate student fellowships were provided by the Chesonis Family Foundation and the Bill and Melinda Gates Foundation. The authors would also like to thank Prof. Jeffrey M. Gordon of Ben-Gurion University of the Negev and Dr. Steve Fantone of Optikos, Inc. for their optical engineering insights, and Prof. Alan Hatton of MIT for his evaluation of the viability of a nanoparticle-based approach to light absorption in molten salts.
